# 1 Introduction

PSOM, pronounced "soam" (the nectar derived from the churning of the oceans in Indian mythology), stands for Process Study Ocean Model. It is a versatile, three-dimensional, non-hydrostatic, computational fluid dynamical model for oceanographic (as well as other) applications (Mahadevan et al., 1996a,b). The model uses the finite volume method on a structured grid with boundary fitted coordinates (topography conforming sigma grid in the vertical, and boundary conforming in the horizontal). The model has a free-surface. It can be used for large- and small-scale phenomena and can be run in hydrostatic or non-hydrostatic mode (Mahadevan, 2006). It uses a highly efficient solution procedure that exploits the skewness arising from the small geometrical aspect (depth to length scale) ratio of the ocean to speed up the solution of the non-hydrostatic pressure, which is solved by the multigrid method.

The model has been used for a number of process studies, including investigation of the vertical transport of nutrients for phytoplankton production (Mahadevan and Archer, 2000) and the dynamics of submesoscale processes (Mahadevan and Tandon, 2006; Mahadevan, Tandon and Ferrari, 2010). Since the non-hydrostatic model is well-posed with open boundaries, it can be used as a nested high-resolution model with time-varying boundary conditions applied from a coarser resolution general circulation model (Mahadevan and Archer, 1998). The model is thus ideally suited for high-resolution, limited-region modeling studies.

## 2 Downloading PSOM

1. Download the latest version of PSOM from GitHub. Users are strongly encouraged to track the modifications and improvements made to PSOM, and to submit them for review through GitHub.
2. Unzip the file into a directory (e.g., `V1.0-master`)
3. Go to the "`V1.0-master/code`" directory and follow the instructions detailed below.

**NOTE :** Hereafter, filepaths are always specified with respect to the directory "`V1.0-master/code`".

## 3 Setting-up PSOM

### 3.1 Fortran compiler and bash profile

Before setting-up PSOM, it is important to make sure that the compiler that will be used to compile PSOM is properly installed. Once the compiler is properly installed, the file `.bash_profile` should be edited to include the proper paths. In the

example below, the `.bash_profile` includes 3 different paths where the compiler could be located (`/opt/intel/composer_xe_2015/bin`, `/usr/local`, and `/opt/intel/bin`) .

```
1 #bash_profile
2
3 # PSOM environment variables
4 export DYLD_LIBRARY_PATH=/opt/intel/lib
5 export PATH=$PATH\:/opt/intel/composer_xe_2015/bin:/usr/local:/opt/intel/
  bin
```

Once you have installed the compiler, you will likely have to modify the compiler flags in `tools/genmakefile1`

## 3.2 `optfile` and `configure.sh`

Before being able to compile PSOM, a few necessary steps must be taken:

### Step 1: Update the `optfile`

Edit the line `"fcomp=..."` to specify the proper compiler (e.g., `ifort`, `pgf95`, etc.). If compiler is modified, the user is encouraged to scan through the `.optfile` to make other necessary modifications (e.g., activation of `gotm` library, `define_parallel` flag, etc.).

### Step 2: Run `configure.sh`

```
1 sh tools/configure.sh
```

Running `configure.sh` will search for `makedepend` (which is necessary to create the makefile). The script will stop if `makedepend` is not installed. The makefile file will only be created if `makedepend` can be called. Therefore, the user should download `makedepend`, which is free and widely accessible. For instance, on mac, you can simply type (if you have `macport` installed):

```
1 sudo port install makedepend
```

If you chose to use `netcdf`, an attempt to use `nc-config` will be tried. If `nc-config` is present, it will be used in order to set the links to `netcdf` libraries appropriately; If not, you can complete this step yourself by linking the executable to the `netcdf` libraries. To do so, edit `.optfile` before going to the next step.

To summarize, This step has 2 effects: (1) modify `optfile`, and (2) customize `namelist`. Failures in running `configure.sh` can likely be avoided by correctly installing `makedepend` and/or `netcdf` libraries.

### 3.3 Getting started with PSOM on Poseidon

If you are using Poseidon (the WHOI HPC system) to run PSOM, start by copying the PSOM folder in the ‘share/mahadevanlab’ folder to your scratch directory. Then, edit the directory where PSOM has been installed to your scratch directory “dirc=/vortexfs1/scratch/[username]/PSOM”. Next, run

```
1 sh tools/configure.sh
```

You can now continue with the next section

## 4 Running PSOM

After properly setting-up PSOM, you can simply follow the “clean, compile, run” sequence:

**clean:** This step is only necessary if a new experiment is compiled. If re-compiling the same experiment, there is no need to run `clean.sh`. `clean.sh` is ran using:

```
1 sh tools/clean.sh
```

**compile:** Running `compile.sh` will (1) create the makefile in the folder `mkfile`, and (2) compile the fortran code. A failure during step 4 most likely indicates that there is an error in the fortran code. `compile.sh` is ran using:

```
1 # To compile PSOM using default setup (cf. superceding trick)
2 sh tools/compile.sh
3
4 # To compile a specific experiment, such as the wiggle test case
5 sh tools/compile.sh wiggle
```

**run:** Runs the executable generated by the compiling step. It uses the `namelist` file to define the experiment’s parameters (e.g., time step, output path, etc.; see Section 6.4).

```
1 # To run the wiggle experiment
2 /exe/nh_wiggle < wiggle/namelist_wiggle
```

## 5 Test Cases

### 5.1 Wiggles

```
1 - wiggle      : This is a testcase with a wiggling front over a flat
    topography.
```

## 5.2 NA

```
1 - NA          : This is a much more complex simulation of three fronts
    that go unstable. This case has particles and tracers for biology.
```

## 5.3 Shelfbreak

```
1 - shelfbreak  : Simulation of the Middle Atlantic Bight shelfbreak with a
    shelf front and a shelfbreak front. The topography includes a sharp
    slope at the break. It shows how to use the "user" namelist.
```

# 6 Setting up your PSOM simulation

## 6.1 Create your experiment directory

For every experiment you want to conduct, create a directory that will contain the source files specific to this experiment. As an example, let's say you want to create an experiment named "my\_experiment". First, create a directory `my_experiment/`, in which you will create two subdirectories `my_experiment/inc` and `my_experiment/src`. You can either create these directories manually, or you can run:

```
1 # Copies the template directory
2 cp -r expe_template my_experiment
```

Whether you are a user or a developer, **you are strongly invited to leave untouched the files contained in `model/`**. This directory is designed to contain the latest version of the model, which is common to every user at a given time. For every routine that will be specific to `my_experiment`, a new subroutine should be created in `my_experiment/src/`. This can be achieved using the following command:

```
1 # Copies the initial conditions subroutine
2 cp model/src/ini_st.f90 my_experiment/src
```

The compiling step (see Section 4) includes a superseding procedure that will take into account the new version of `ini_st.f90` (in `my_experiment/src/`) and disregard the standard version found in `model/src/`. More precisely, it will create the makefile based on this new state of the model (in `./mkfile`), compile and create the executable `exe/nh_my_experiment`. More details on `compile.sh` may be found by running:

```
1 # Provides more information on compile.sh
```

### Superseding trick

When compiling, priority is given to the routines present in the experiment folder, over the source code present in `model/src/`. For example, if the wiggle experiment is compiled, any routines located in `wiggle/src/` will be used over the matching routines located in `model/src/`.

```
2 sh tools/compile.sh --help
```

## 6.2 Defining your model grid

The grid size is defined in `size.h`. If you wish to modify the grid size, you must first copy `size.h` into your experiment's directory:

```
1 # Copies the grid file
2 cp model/inc/size.h my_experiment/inc
```

Grids used in previous experiments are listed in this file and commented out. If your grid appears in a commented line, Comment the uncommented line and uncomment the one you want. Be aware that if your grid set requires more than 2Go, you might experience compilation issues. If so, you may fix the issue by editing `tools/genmakefile1` to replace the default compiling options by:

```
fflags_o="-fpp -real-size 64 -mcmmodel medium -shared-intel -stand 03 -u"
fflags_e="-fpp -real-size 64 -mcmmodel medium -shared-intel -stand 03 -u"
```

If your grid set does not appear in `my_experiment/inc/size.h`, you can create the required line. Defining the model grid is not straight-forward, because of the multi-grid solver `mgrid` **<FIX ME: (See Section)>**. The multi-grid solver is used to allow the reuse of array space in `mgrid.f90` **<FIX ME: insert link to function?>**. Although this issue could now be circumvented by making use of `f90`'s dynamic allocation of memory, the code was originally in `fortran77`, explaining the need for space re-allocation. A step-by-step approach to defining your own grid is provided below:

1. Choose grid dimensions  $NI$ ,  $NJ$ , and  $NK$  (i.e., the number of grid cells in  $x$ ,  $y$ , and  $z$  directions) such that the grid can be subdivided a maximum number of times by a factor of 2 to form " $ngrid$ " levels of grid. For example, choosing  $NI = 48$ ,  $NJ = 24$ , and  $NK = 32$  constrains the grid levels to 4 (i.e.,  $ngrid = 4$ ), because:

$NI : 48; 24; 12; 6; 3$	(5 grid levels)
$NJ : 24; 12; 6; 3$	(4 grid levels)
$NK : 32; 16; 8; 4; 2$	(5 grid levels)

The number of grid points possible for a specific  $ngrid$  can be computed by multiplying prime numbers (2, 3, 5, 7, etc.) by  $2^{ngrid-1}$ . Table 1 lists some of the most commonly used number of grid points, depending on the number of grid levels  $ngrid$ .

2. Compile `tools/preproc.f90`:

```
1 # Compiles preproc.f90 (e.g., using ifort)
2 ifort preproc.f90 -o preproc
```

3. Runs `preproc.f90` and fill the values that are asked:

```
1 # Runs preproc
2 ./preproc
```

4. Copy/Paste the last line the program provides in `my_experiment/inc/size.h`.  
Below is an example for  $NI = 96$ ,  $NJ = 160$ , and  $NK = 32$  (hence  $ngrid = 5$ , see Table 1):

```
1 ./preproc
2 number of grid levels in mgrid, ngrid =
3 5
4 input the grid info
5 NI =
6 96
7 NJ =
8 160
9 NK =
10 32
11 Number of grid points on fine grid: nx,ny,nz   96   160   32
12 m, ntint, ntout, nbc(m) 1      491520      539784      47104
13 m, ntint, ntout, nbc(m) 2      61440       73800      11776
14 m, ntint, ntout, nbc(m) 3       7680      10920       2944
15 m, ntint, ntout, nbc(m) 4       960       1848        736
16 m, ntint, ntout, nbc(m) 5       120        384       184
17 Copy the following line to size.h
18 INTEGER, PARAMETER :: NI=96, NJ=160, NK = 32, ngrid=5, maxout
    =626736, maxint=561720, int1=491520
```

## 6.3 `cppdefs.h`

This file defines the different options to be used in the experiment. Again, it is recommended to copy this file into the experiment folder (e.g., `my_experiment/inc/` before making any modifications. To include (exclude) an option, use `#define` (`#undef`) *option\_name*. The file includes 13 options:

*runtracmass* : placeholder

*periodic\_ew* : placeholder

Table 1: Number of grid points associated with a specific number of grid levels  $ngrid$ . These numbers can be computed by multiplying prime numbers (2, 3, 5, 7, etc.) by  $2^{ngrid-1}$ . Each experiment's number of grid levels is set by the minimum  $ngrid$  associated with  $NI$ ,  $NJ$ , and  $NK$ .

$ngrid$	Number of grid points ( $NI$ , $NJ$ , or $NK$ )							
4	16	24	40	56	88	104	136	152
5	32	48	80	112	176	208	272	304
6	64	96	160	224	352	416	544	608
7	128	192	320	448	704	832	1088	1216

*periodic\_ns* : placeholder

*allow\_particle* : If defined, allows the seeding of particles in the experiment. Please refer to section **<FIX ME: ref to particle section>** for a detailed explanation on particle seeding.

*rhoonly* : If defined, only the density field  $\rho$  is used. The density field is stored in the salinity array ( $s$ ; see `evalrho_rho.f90`). If not defined,  $\rho$  is computed from the salinity ( $s$ ) and temperature ( $T$ ) fields (see `evalrho_ST.f90`).

*relaxation* : placeholder

*bottom\_thickness* : placeholder

*file\_output* : placeholder

*file\_output\_cdf* : placeholder

*file\_output\_bin* : placeholder

*gotm\_call* : placeholder

*implicit* : placeholder

*parallel* : placeholder

## 6.4 namelist

This file defines key parameters relating to the experiment (e.g., grid resolution, time step, diffusion, output, ...). Again, it is recommended to copy this file into the experiment folder (e.g., `my_experiment/` before making any modifications. Each parameter in the file is either self-explanatory or include a short description as a comment.

!!!!!! Updated upstream

## 6.5 Defining the initial conditions

Initial conditions can be specified either in the corresponding subroutines, or from an input file. The former approach is used in the Shelfbreak test-case (see Section 5.3), where the temperature and salinity distributions are determined from analytical expressions in DO-loops, and only requires a limited knowledge of the model grid. The latter approach can sometimes be more practical, especially when using available data products to initialize the model. However, this approach requires mapping the data used to initialize the experiment to the pre-defined model grid.

The horizontal grid is relatively straightforward to determine, given the grid size specified in `my_experiment/inc/size.h` (i.e.,  $NI$  and  $NJ$ ), and the grid resolution specified in `my_experiment/namelist` (i.e.,  $dx$  and  $dy$ ). The location of each grid point can be computed using the following equations:

$$x(i) = -dx/2 + idx; \quad i = (0, 1, 2 \dots NI, NI + 1) \quad (1)$$

$$y(j) = -dy/2 + jdy; \quad j = (0, 1, 2 \dots NJ, NJ + 1) \quad (2)$$

The initial conditions in the temperature and salinity: Talk about the rhoonly flag, the way to set initial conditions, etc...

!!!!!! Updated upstream

## 6.6 Wind stress

To specify a customized wind forcing, the code in `wind_stress.f90` can be modified. The wind stress at the surface is prescribed to the model through the variables `stress_top_x`, `stress_top_y`, and `stress_top`. The dimensions of these three variables are  $(NI, NJ)$  (see `header.f90`). The surface wind stress can be read from a file:

```
1 ! Import the wind stress time series for model forcing
2 if (step.eq.1) then
3   open(unit=17, file='youfilefullpath.in')
4   do i=1,nsteps
5     read(17,fmt="(F5.10,F5.10)") stressxTS(i),stressyTS(i)
6   end do
7   close (17)
8   PRINT*,"Read wind stress"
9 end if
10 stress_top_x = stressxTS(step)
11 stress_top_y = stressyTS(step)
```

or specified as a constant:

```
1 stress_top_x = 0.05d0
2 stress_top_y = 0.01d0
3 PRINT*,"Read Wind Stress"
```

If your domain includes solid boundary (i.e., no periodicity), it is recommended to damp the surface wind stress close to the boundaries, to avoid upwelling/downwelling. Below is an example of wind stress damping at the north/south boundaries using a tanh profile. A similar approach can be used in the east/west direction.

```

1 ! Apply a tanh profile in the meridional direction
2 ycenter = 0.5*(yc(NJ)+yc(1)) ! Find the middle of the domain
3 ywindmin = 10.0 ! Starts damping 10 km from southern boundary
4 ywindmax = yc(NJ)-10.d0 ! Starts damping 10 km from northern
   boundary
5 edge = 0.06 ! tightness of the padding in the wind stress
6
7 do j=1,NJ
8   if (yc(j).lt.yc(NJ/2)) then
9     stressprofile(j) = 0.5*(tanh(edge*(yc(j)-ywindmin)*PI)+1.d0)
10  else
11    stressprofile(j) = -0.5*(tanh(edge*(yc(j)-ywindmax)*PI)-1.d0)
12  end if
13 end do
14
15 do j=1,NJ
16   do i=1,NI
17     stress_top_x(i,j) = stressxTS(step)*stressprofile(j)
18     stress_top_y(i,j) = stressyTS(step)*stressprofile(j)
19   end do
20 end do

```

## 6.7 Surface Heat Fluxes

## 6.8 Adding your own modules

If you want to add additional scripts to PSOM, they need to be added to the optfile in order to be recognized by the compiler. You can do this using a file ‘optfile.add’ that is placed at the same level as your namelist (and src and inc folders). Within this file, place the command

```
lobj$_$additional=script1.o script2.o
```

# 7 Particle tracking in PSOM

PSOM offers the option to release and track particles ”online” (i.e., as part of the numerical simulation). To activate this option, the allow\_particle options must be defined in inc/cppdefs.h by including (See Section 6.3):

```
#define allow_particle
```

The particle tracking code has been written for a rectangular grid only, and cannot be used “as is” for a non-rectangular model grid.

## 7.1 Non-sinking particles

While key particle parameters are set in `namelist` (e.g., particle number, frequency of outputs, etc.; see Section 7.4), the seeding and advection of particles is controlled by the code included in `particles.f90`. The file includes the following subroutines:

- open\_parti\_files*: This subroutine creates the output files where the particle characteristics will be saved. The number of output files is specified in `namelist` and must be a factor of the total number of particles ( $NPR$ ). Increasing the number of output files reduced the size of the individual files, which proves to be useful when dealing with a very large number of particles. The output files are unformatted binary files.
- save\_parti*: This subroutine loops through all the particles and writes the specified variables. The number of variables saved is important, as it must be known to read the unformatted binary output files.
- ini\_particles*: This subroutine is called when the model timestep matches the particle initialization timestep specified in `namelist`. This is where the seeding of particle is defined. By default, all particles are released below the surface layer in the middle of the model domain. To personalize the release of particles, see Section 7.4.2.
- get\_parti\_vel*: This subroutine interpolates the physical model’s velocity field onto the particles’ positions (using *interp\_trilinear*; see below). The *get\_parti\_vel* subroutine also interpolates variables of interest onto the particles position (e.g., salinity, temperature, density, vorticity, etc.).
- parti\_forward*: This subroutine extrapolates the position of a particle at the next timestep  $t+1$  using a  $2^{nd}$  order Adams-Bashforth scheme. As an example, the position of the particle in the zonal direction is computed using:

$$(i, j, k)_{t+1} = (i, j, k)_t + dtf \times \frac{1}{2}[3(u, v, w)_{t+1} - (u, v, w)_t]$$

Where  $(i, j, k)$  is the position of the particle in the model space,  $dtf$  is the non-dimensional model time step,  $(u, v, w)$  is the non-dimensional velocity field at the particle’s location, and the subscripts represent the timestep. The corresponding code appears in `particles.f90` as (e.g., for the particle position in the zonal direction):

```

1  ! Assign i-position to particle.
2  parti(i)%i = parti(i)%i + 0.5d0 * dtf * (3d0 * parti(i)%u - parti(
    i)%u0)
```

At  $t=0$ , the velocities are assumed to be zero (set in *ini\_particles*, and the 2<sup>nd</sup> order Adams-Bashforth scheme simplifies to a one-step Euler scheme.

*interp\_trilinear* This subroutine is used to interpolate 3D model variables onto a particle's position using a trilinear interpolation technique (e.g., velocities, density, etc.).

*interp\_bilinear* This subroutine is used to interpolate 2D model variables onto a particle's position using a bilinear interpolation technique (e.g., depth of water column).

## 7.2 Sinking particles

The subroutine *get\_parti\_vel* includes the possibility to prescribe a vertical sinking velocity to the particles (set to 0 m/s by default). The prescribed velocity must be scaled appropriately to match the scaling used by PSOM. This requires information about the function used to compute the thickness of the model cells in the vertical, defined in *findzall.f90*. If this function is modified, the code in *particles.f90* **must be changed accordingly** (See Appendix A for important information). Although not implemented in the code, a horizontal velocity (e.g., to simulate swimming behavior) could also be easily prescribed to the particles following a similar method.

## 7.3 Reading unformatted binary output files

Particle-tracking output files are written as unformatted binary files. Information on how the output file is built is therefore required to be able to access the data. Two MATLAB routines to import or convert the particle-tracking output are provided with the model code:

- *particle\_open\_bin.m*: Imports the particle-tracking data into MATLAB as a 3D matrix (Nbr of particles, model time, # of recorded variables; see Appendix B). WARNING: This routine SHOULD NOT BE USED FOR LARGE FILES otherwise the 3D matrix will become too large and will crash MATLAB.
- *particle\_bin2csv.m*: Converts the particle-tracking data into a CSV-file (see Appendix C). This can be helpful when trying to import the particle-tracking data into another software (i.e., into an SQL database).

## 7.4 Customizing Particle-tracking in PSOM

### 7.4.1 Parameters in *namelist*

To set up a particle-tracking experiment in PSOM, the *allow\_particle* option must be defined in *inc/cppdefs.h* (See Section 6.3):

```
#define allow_particle
```

Four key variables related to particle-tracking are set in the `namelist` file:

1. The total number of Particles ( $NPR$ ).  $NPR$  must be a multiple of the number of output files (see below).
2. The time step at which the particles are released (`ini_particle_time`). `ini_particle_time` **must be** greater than 0, or than `pickup_step` if pickup files are used to initialize the experiment (see Section 6.4 **<FIX ME: Refer to section about namelist and pick up files>**). If `ini_particle_time = pickup_step`, no particle output file will be written.
3. The number of output files to generate (`parti_file_num`). Increasing the number of files logically decreases the file size. This is especially useful when dealing with a very large number of particles, or when writing particles' position at high frequency. The number of file must be a factor of  $NPR$  (see above).
4. The frequency of particle outputs (`parti_outfreq`) in number of time steps.

## 7.4.2 particles.f90

### a. Particle seeding

The seeding and tracking of the particles in PSOM are controlled by subroutines located in `particles.f90`. To personalize the seeding of particles in the model, the code in the subroutine `ini_particles` should be altered. By default, the particles are released below the surface layer, in the middle of the model domain:

```

1  ! User-defined particle positioning.
2  DO ip=1, NPR
3    parti(ip)%i=REAL(NI)/2d0 ! mid-domain in x
4    parti(ip)%j=REAL(NJ)/2d0 ! mid-domain in y
5    parti(ip)%k=REAL(NK)-5. ! sub-surface cell
6    =====

9    >>>>>> Stashed changes
10   >>>>>> Stashed changes
11
12   ! Converts model grid to distances (i,j,k) ==> (x,y,z)
13   parti(ip)%x = parti(ip)%i * dx
14   parti(ip)%y = parti(ip)%j * dy
15   ! Assign z-position to particle based on sigma level
16   ! Calculate the scaled z-depth
17   CALL sigma2z(parti(ip)%i, parti(ip)%j, parti(ip)%k, swap1)
18   parti(ip)%z = swap1 * DL
19 ENDDO

```

## b. Sinking velocity

A sinking velocity can be prescribed to the particles (default = 0 m/s) by modifying the following line of code in *get\_parti\_vel*:

```
1 ! Then, specify the sinking velocity (in m/s), including the scaling
  factors
2 parti(ip)%wsink= -0d0/86400d0/WL*parti(ip)%wzf*EPS ! 0 m/day
```

## 8 Coupling PSOM with GOTM

PSOM can be coupled with the 1D water column general ocean turbulence model (GOTM) if you would like to use various mixing schemes such as KPP,  $K - \epsilon$ , etc.

### 8.1 Compile GOTM

1. First, download GOTM from <https://gotm.net/>
2. Set up the following 2 environmental variables in your `.bashrc` (or `.bash_profile`), which should reside in your home directory

```
1 export FORTRAN_COMPILER=IFORT
2 export GOTMDIR=/home/sr71d/PSOM/github/psom-gotm/gotm-4.0.0
3
4 # the GOTMDIR variable should contain the directory where you build
  gotm
```

3. Within `src`, type the following commands:

```
1 make distclean # this removes libraries from previous
  compilations
2 make          # this creates fresh libraries on your machine
3
```

4. After the previous step, there should be libraries in the `lib` folder. If you use the intel fortran compiler, the libraries will be in the `lib/IFORT` folder. If you use the gfortran compiler, the libraries will be created in `lib/gfortran`. The following libraries should have been created:

```
1 libairsea_prod.a libmeanflow_prod.a libseagrass_prod.a
2 libbio_prod.a libobservations_prod.a libturbulence_prod.a
3 libgotm_prod.a liboutput_prod.a libutil_prod.a
4
```

If you see the above GOTM libraries are built, congrats! Now we can move on to compiling PSOM with GOTM.

## 8.2 Compiling PSOM with GOTM

There are a few options we need to change in order to couple GOTM and PSOM. In PSOM, we need to:

1. In the `optfile`, set `define-gotm = T` and specify the path to where the gotm libraries are found
2. Make a new experiment in PSOM, and in the `inc/cppdefs.h` file, make sure the following options are selected:

```
#define gotm_call
#define implicit
```

3. From here, clean, compile, and execute the experiment as normal.

## 8.3 Other notes

- To switch between different turbulence models, change the “`turb_method`” flag in the `gotmturb.nml` file.
- If the flag is set to KPP, may need an additional input file to define parameters (see <https://github.com/PSOM/V1.0/blob/master/code/gotmturb.nml>)
- right now, running PSOM with implicit mixing is much slower than explicit mixing.

# 9 Modifying grids with bottom topography

## 9.1 The vertically stretched sigma-grids

In general, a vertical stretching is applied to the grids

$$z = \frac{\exp\left(\frac{N_{top}-\sigma}{N_{top}-N_{bot}}p\right) - 1}{\exp(p) - 1}(D_{bot} - D_{top}) + D_{top}, \quad (3)$$

where  $\sigma = 1, 2, \dots, Nk$  is the vertical index of the grid cell,  $N_{top}$  and  $N_{bot}$  are the vertical indices of the top and bottom boundaries, respectively,  $D_{top}$  and  $D_{bot}$  are the z-coordinates (negative values for the ocean) of the top and bottom boundaries, respectively, and  $p$  is a factor that controls the strength of the stretching. The greater  $p$ , the more stretching. In the code,  $p$  is represented by `pfac`. One can check that when  $\sigma = N_{bot}$ ,  $z = D_{bot}$ ; and when  $\sigma = N_{top}$ ,  $z = D_{top}$ . (Figure 1)

and `epmlinv` are the multiplicative inverses of `dnkm1` and `epm1`, respectively. Thus (3) reads (the same for `zf`)

```
1  xfac = (dnkm1-sigma)*dnkm1inv
2  zc(i,j,k) = (exp(pfac*xfac)-1.d0)*epmlinv*(D(i,j)+dzbot+dztop)-dztop
```

Listing 1: `findz_topmoves.f90`

## 9.2 Derivatives of sigma

We write  $\sigma$  in terms of  $z$

$$\frac{z - D_{top}}{D_{bot} - D_{top}} = \frac{\exp\left(\frac{N_{top} - \sigma}{N_{top} - N_{bot}}p\right) - 1}{\exp(p) - 1},$$

$$\frac{(z - D_{top})[\exp(p) - 1]}{D_{bot} - D_{top}} + 1 = \exp\left(\frac{N_{top} - \sigma}{N_{top} - N_{bot}}p\right),$$

$$\log\left\{\frac{(z - D_{top})[\exp(p) - 1]}{D_{bot} - D_{top}} + 1\right\} = \frac{N_{top} - \sigma}{N_{top} - N_{bot}}p,$$

$$\sigma = N_{top} - \frac{N_{top} - N_{bot}}{p} \log\left\{\frac{(z - D_{top})[\exp(p) - 1]}{D_{bot} - D_{top}} + 1\right\},$$

then take the  $z$ -derivative

$$\begin{aligned} \frac{\partial \sigma}{\partial z} &= -\frac{N_{top} - N_{bot}}{p} \left\{ \frac{(z - D_{top})[\exp(p) - 1]}{D_{bot} - D_{top}} + 1 \right\}^{-1} \frac{\exp(p) - 1}{D_{top} - D_{bot}} \\ &= -\frac{N_{top} - N_{bot}}{p} \frac{D_{bot} - D_{top}}{(z - D_{top})[\exp(p) - 1] + D_{bot} - D_{top}} \frac{\exp(p) - 1}{D_{top} - D_{bot}} \\ &= -\frac{N_{top} - N_{bot}}{p} \frac{\exp(p) - 1}{(z - D_{top})[\exp(p) - 1] + D_{bot} - D_{top}}. \end{aligned} \quad (4)$$

In the code `staticsigma.f90`,  $\frac{\partial \sigma}{\partial z}$  appears as `wz` for cell centers and `wzk` for cell faces. As in `findz_topmoves.f90`, if a fixed bottom thickness is defined, `dnkm1` equals `Nk-2`; otherwise, `dnkm1` equals `Nk-1`. The term `dnkm1p` is `dnkm1/pfac` in short. `zpd` and `hpd` represent `z+dztop` and `D+dztop`, respectively. Thus (4) reads (the same for `wzk`)

```
1  wz(i,j,k) = -epm1*dnkm1p/(epm1*zpd+hpd)
```

Listing 2: `staticsigma.f90`

Using the chain rule, the horizontal derivatives of  $\sigma$  are

$$\frac{\partial \sigma}{\partial x_i} = \frac{\partial \sigma}{\partial z} \frac{\partial z}{\partial D} \frac{\partial D}{\partial x_i} = \frac{\partial \sigma}{\partial z} \frac{z - D_{top}}{D_{bot} - D_{top}} \frac{\partial D}{\partial x_i} \quad (5)$$

In the code `staticsigma.f90`,  $\frac{\partial \sigma}{\partial x}$  and  $\frac{\partial \sigma}{\partial y}$  are expressed by `wx` and `wy` for cell centers, respectively, and `wxk` and `wyk` for cell faces, respectively. The term `hpdinv` is the multiplicative inverse of `hpd`. Thus (5) reads

```

1  wx(i,j,k)= wz(i,j,k)*zpd*hpdinv*Ddx(i,j)
2  wy(i,j,k)= wz(i,j,k)*zpd*hpdinv*Ddy(i,j)
3  ...
4  temp= (epml*dnkm1p/(epml*zpd+hpd))*zpd*hpdinv
5  wxk= Ddx(i,j)*temp
6  wyk= Ddy(i,j)*temp

```

Listing 3: `staticsigma.f90`

### 9.3 The modified vertical grids

We propose a new four-section grids that are composed of the top, upper, lower, and bottom layers. As the original grids, the top layer is the free surface and bottom layer is the frictional boundary layer. We define a flat depth `Df`, where layers above it are flat, having no variations in the horizontal, while layers below it are corrugated, gradually align with the topography when approaching the bottom. We select the number of layers below the flat depth to be `Nf` so that the modified vertical grids are as sketched in Figure 2.

**The upper layer** In (3),  $N_{top}$  and  $N_{bot}$  are replaced by  $Nk-1$  and  $Nf$ , respectively, and  $D_{top}$  and  $D_{bot}$  are replaced by  $-dz_{top}$  and  $Df$ , respectively

$$z = \frac{\exp\left(\frac{Nk-1-\sigma}{Nk-1-Nf}p\right) - 1}{\exp(p) - 1}(Df + dz_{top}) - dz_{top}. \quad (6)$$

In the code `findz_topmoves.f90`, `dnkm1` is always  $Nk-1$ . Thus (6) reads (the same for  $z_f$ )

```

1  xfac = (dnkm1-sigma)/(dnkm1-Nf)
2  zc(i,j,k) = (exp(pfac*xfac)-1.d0)*epmlinv*(Df+dztop)-dztop

```

Listing 4: `findz_topmoves.f90` (for the upper layer)

**The lower layer** In (3), if a fixed bottom thickness is defined,  $N_{top}$  and  $N_{bot}$  are replaced by  $Nf$  and 1, respectively, and  $D_{top}$  and  $D_{bot}$  are replaced by  $Df$  and  $D+dz_{bot}$ , respectively; otherwise,  $N_{top}$  and  $N_{bot}$  are replaced by  $Nf$  and 0, respectively, and  $D_{top}$  and  $D_{bot}$  are replaced by  $Df$  and  $D$ , respectively

$$z = \frac{\exp\left(\frac{Nf-\sigma}{Nf}p\right) - 1}{\exp(p) - 1}(D - Df) + Df. \quad (7)$$

In the code `findz_topmoves.f90`, again we define a new index `dnf` for the flat depth: if a fixed bottom thickness is defined, `dnf` equals `Nf-1`; otherwise, `dnf` equals `Nf`. The term `dnfinv` is the multiplicative inverse of `dnf`. Thus (7) reads (the same for `zf`)

```
1 xfac = (dnf-sigma)*dnfinv
2 zc(i,j,k) = (exp(pfac*xfac)-1.d0)*epmlinv*(D(i,j)+dzbot-Df)+Df
```

Listing 5: `findz_topmoves.f90` (for the lower layer)

## 9.4 The modified derivatives of sigma

**The upper layer** The vertical derivative of  $\sigma$  is

$$\frac{\partial \sigma}{\partial z} = -\frac{Nk-1-Nf}{p} \frac{\exp(p)-1}{(z+dztop)[\exp(p)-1]+Df+dztop}. \quad (8)$$

In the code `staticsigma.f90`, `dnkm1` is always `Nk-1`. Thus (8) reads (the same for `wzk`)

```
1 wz(i,j,k) = -epml*(dnkm1-dnf)/pfac/( epml*zpd+(Df+dztop) )
```

Listing 6: `staticsigma.f90` (for the upper layer)

The horizontal derivatives are always zeros since grids are rectilinear in the horizontal (the same for `wxk` and `wyk`)

```
1 wx(i,j,k)= 0.d0
2 wy(i,j,k)= 0.d0
```

Listing 7: `staticsigma.f90` (for the upper layer)

**The lower layer** The vertical derivative of  $\sigma$  is

$$\frac{\partial \sigma}{\partial z} = -\frac{Nf}{p} \frac{\exp(p)-1}{(z-Df)[\exp(p)-1]+D-Df}. \quad (9)$$

In the code `staticsigma.f90`, if a fixed bottom thickness is defined, `dnf` equals `Nf-1`; otherwise, `dnf` equals `Nf`. The term `dnfp` is `dnf/pfac` in short. Thus (9) reads (the same for `wzk`)

```
1 wz(i,j,k) = -epml*dnfp/( epml*(z-Df)+(D(i,j)+dzbot-Df) )
```

Listing 8: `staticsigma.f90` (for the lower layer)

For the horizontal derivatives, we replace  $D_{top}$  and  $D_{bot}$  in (5) by `Df` and `D+dzbot`, respectively. Thus in the code `staticsigma.f90`,

```

1 wx(i,j,k)= wz(i,j,k)*(z-Df)/(D(i,j)+dzbot-Df)*Ddx(i,j)
2 wy(i,j,k)= wz(i,j,k)*(z-Df)/(D(i,j)+dzbot-Df)*Ddy(i,j)
3 ...
4 temp= epml*dnfp/( epml*(z-Df)+(D(i,j)+dzbot-Df) ) *(z-Df)/(D(i,j)+
dzbot-Df)
5 wxk= Ddx(i,j)*temp
6 wyk= Ddy(i,j)*temp

```

Listing 9: staticsigma.f90 (for the lower layer)

$h$  is the free surface height  
 $D$  is the sea depth, as a function of  $x$  and  $y$   
 $D_f$  is the depth of the first flat surface from below, as a constant  
 $N_k$  is the total # of grids in the vertical  
 $N_f$  is the number of corrugated layers

Figure 2: Schematic plot of the modified vertical grids

## **A   Appendix A**

# Prescribing Sinking Velocity to Particles

M.Dever

July 18, 2017

## How is sinking prescribed

The sinking velocity in the model ( $w_{sink}$ ) is prescribed in the subroutine `get_parti_vel` in `particles.f90`. To match the physical model's velocity,  $w_{sink}$  must be scaled appropriately using:

```
1 parti(ip)%wsink= -ld0/86400d0/WL*parti(ip)%wzf*EPS ! lm/day
```

where  $WL$  non-dimensionalizes the vertical velocity,  $EPS$  is the Rossby number, and  $wzf$  is the coefficient scaling the vertical velocity with the size of the the  $k$ -cell in the  $k$ -space.

### More on wzf

$wzf$  can be thought of as  $1/\Delta z$ . It is the inverse of the (normalized) grid spacing in the vertical **at the cell faces**. The equivalent metric at the cell centers is  $wz$ .

## Error on the vertical displacement

### Motivation

The coefficient  $wzf$  needs to be determined for each particle position. The original way of determining  $wzf$  relied on (1) the linear interpolation of the cell-centered vertical grid spacing  $wz$ , and (2) the trilinear interpolation used in the particle code (see `particles.f90`).

```
1 ! Compute wz at face grids using linear interpolation
2 wzf = 0.5d0*(wz(:, :, 0:NK) + wz(:, :, 1:NK+1))
3
4 ! Compute wzf at the particle's location using trilinear interpolation
5 CALL interp_trilinear(dic,djc,dkc,wzf(ic:ic+1,jc:jc+1,kc:kc+1),parti(ip)%wzf)
```

### Issues

The approach to determine the  $wzf$  coefficient onto the particle position in the vertical introduced some error in the vertical position of the particle. This error was identified by comparing the depth of a particle sinking at a constant rate as computed by the `particles.f90` routine, with the theoretical depth based on the sinking rate, the time elapsed, and the release depth:

```
1 model = w_sink * (t - t0) + z0
```

Figure 1 shows the error on the particle's vertical positioning with respect to the particle's depth. The error increases between the cell centers and faces (where the velocity is underestimated; see Figure 1), and decreases between cell faces and centers (where the velocity is overestimated). The error therefore oscillates and grows as k-cells become thicker. Future model variables (i.e., current velocities) will be interpolated onto the erroneous particle position, therefore introducing some cumulative effect in the errors associated with this method. Such errors are hard to quantify.

Figure 1: Error on particle vertical position due to the interpolation of  $wzf$  onto the particle position. Error is maximum at model grid cell centers and at grid cell faces. Error grows with depth, as grid cells become thicker, and is independent of the sinking velocity. Right panel shows the important variables and highlights the limitations of the original method.

## New approach

Instead of relying on an interpolation of the discrete values of  $wzf$ , the continuous function that determines the depth of the k-levels (i.e., the vertical grid spacing), is used to exactly determine the value of  $wzf$  at the particle's location. The function is defined in the routine `findz_topmoves.f90`.

```
1  zc(i,j,k)= (exp(pfac*xfac)-1.d0)*epmlinv*(D(i,j)+dztop) -dztop
```

which can be re-written in terms of set parameters as:

$$zc(i,j,k) = \left( \frac{D(i,j) + dztop}{e^{pfac} - 1} \right) e^{pfac} e^{\frac{-pfac(k-0.5)}{NK-1}} + C \quad (1)$$

where  $zc$  is the depth of the cell-center,  $D(i,j)$  is the dimensionless depth of the 0-th face  $z$  (at cell centers in  $x$  and  $y$ ),  $dztop$  is the dimensionless thickness of the uppermost cell,  $pfac$  is the vertical stretching parameter used to define the sigma levels,  $NK$  is the number of vertical levels, and  $C$  is a constant.

## What about the horizontal?

The error in the vertical described here arises from the fact that cell dimensions change with depth. A similar issue will therefore be present in the horizontal when using a non-rectangular grid. For a non-rectangular grid,  $uxf$  and  $vyf$  should be computed using a similar approach than the method outlined below. For a rectangular grid, the linear interpolation of  $ux$  and  $vy$  onto the faces is adequate.

## What is the constant C?

The value of  $C$  is irrelevant in this context, as the difference between two  $z$ -levels is the quantity we are ultimately interested in.

The equation for the difference between two z-levels at  $k$  and  $k+1$  (i.e.,  $\Delta z$ ) can thus be derived (Figure 2):

$$zc|_k = \left( \frac{D + dz_{top}}{e^{pfac} - 1} \right) e^{pfac} e^{-\frac{pfac(k-0.5)}{Nk-1}} + C = \left( \dots \right) e^{pfac} e^{\frac{\frac{1}{2}pfac}{Nk-1}} e^{-\frac{pfac k}{Nk-1}} + C$$

$$zc|_{k+1} = \left( \dots \right) e^{pfac} e^{-\frac{pfac(k+0.5)}{Nk+1}} + C = \left( \dots \right) e^{pfac} e^{\frac{\frac{1}{2}pfac}{Nk+1}} e^{-\frac{pfac k}{Nk+1}} + C$$

$$\Delta z = zc|_{k+1} - zc|_k = \left( \dots \right) e^{pfac} e^{-\frac{pfac k}{Nk+1}} \left( e^{\frac{\frac{1}{2}pfac}{Nk+1}} - e^{\frac{\frac{1}{2}pfac}{Nk-1}} \right) + C - C$$

Figure 2: Equations used to compute  $\Delta z$  at  $k$ -faces in particles.f90

The variable  $wzf$  can now be computed exactly at the particle's position by taking the inverse of  $\Delta z$ . Figure 3 shows the error (in meters, as well as in percentage of the particle's depth) on the particle vertical position after modifying the approach to compute  $wzf$ . The error grows linearly with depth, with a slope of  $1.735 \times 10^{-4}$  m per meter (i.e., 17.35 cm at 1000 m deep).

Figure 3: Error on particle vertical position after the approach used to compute  $wzf$  was modified.

#### What about the horizontal?

A slightly different equation than the one depicted in Figure 2 must be used if computing  $wz$ . While  $wzf$  must be computed using the depth of the z-cell centers  $zc$ ,  $wz$  must be computed using the depths of the z-cell faces  $zf$ . this is achieved by using  $k$  instead of  $(k - 0.5)$  in Equation 1.
